a. The reported values assume that the proteins are long-lived compared to the generation time but are unable to account for post-translational modifications that may alter absolute protein abundances.

b. This mass spectrometry approach differs substantially from the others since in addition to the relative proteome-wide abundance measurements, the authors performed absolute quantification of 41 proteins across all growth conditions (see Section Schmidt *et al.* Proteomic Data Set for more details on this).

Summary of Proteome Datasets.

Here we provide a brief summary of the experiments behind each proteomic data sets. The purpose of this section is to better identify the steps taken by the authors to arrive at absolute protein abundances. In the following section (Section Summary of Proteomic Data Sets) we will then provide a summary of the final protein abundance measurements that were used for in the main text. Table ?? provides an overview of the main data sets that we considered. These are predominately mass spectrometry-based, with the exception of the work from Li *et al.* (2014) which used ribosomal profiling, and the fluorescence-based counting done in Taniguchi *et al.* (2010).

Fluorescence based measurements of protein abundance

In the work of Taniguchi *et al.* (2010), the authors used a chromosomal YFP fusion library where individual strains have a specific gene tagged with a YFP-coding sequence. 1018 of 1400 attempted strains were used in their work. For each strain, a fluorescence microscope was used to collect cellular YFP intensities. Through automated image analysis, the authors normalized intensity measurements by cell size to account for the change in size and expression variability across the cell cycle. YFP intensities were also corrected for cellular autofluorescence, and final absolute protein levels were determined by a calibration with single-molecule fluorescence intensities, performed separately using a purified YFP solution.

Ribosomal profiling measurements of protein abundance

The work of Li *et al.* (2014) takes a sequencing based approach to estimate protein abundance. Ribosomal profiling, which refers to the deep sequencing of ribosome-protected mRNA fragments, provides a quantitative measurement of the protein synthesis rate. As long as the protein life-time is long relative to the cell doubling time, it is possible to also estimate absolute protein copy numbers.

To perform ribosomal profiling, ribosome-protected mRNA is extracted from cell lysate and selected on a denaturing polyacrylamide gel, and sequences are obtained by deep sequencing (15–45 nt long fragments collected and sequenced by using an Illumina HiSeq 2000 in Li *et al.* (2014)). Counts of ribosome footprints from the sequencing data are corrected empirically for position-dependent biases in ribosomal density across each gene, as well as dependencies on specific sequences including the Shine-Dalgarno sequence. These data-corrected ribosome densities represent relative protein synthesis rates.

Absolute protein synthesis rates are obtained by multiplying the relative rates by the total cellular protein per cell. The total protein per unit volume was determined with the Lowry method

to quantify total protein, calibrated against bovine serum albumin (BSA). By counting colony-forming units following serial dilution of their cell cultures, they then calculated the total protein per cell. The absolute protein synthesis rate has units of proteins per generation, and for stable proteins will also correspond to the protein copy number per cell.

Mass spectrometry measurements of protein abundance

Unsurprisingly, the data is predominantly mass spectrometry based, largely due to the tremendous improvements in sensitivity of instruments over the last decade, as well as improvements in sample preparation and data analysis pipelines. It is now a relatively routine task to extract protein from a cell and quantify the majority of proteins by shotgun proteomics. In general, this involved lysing cells, enzymatically digesting the proteins into short peptide fragments, and then introducing them into the mass spectrometer (commonly employing liquid chromatography and electrospray ionization), which itself can have multiple rounds of detection and further fragmentation of the peptides.

Most quantitative experiments rely on labeling protein with stable isotopes, which allow multiple samples to be measured simultaneously by the mass spectrometer. By combining samples of known total protein abundance (i.e. one sample of interest, and one reference), it is possible to determine relative protein abundances. With relative protein abundances in hand, absolute protein abundances can be estimated following the same approach used above for ribosomal profiling, which is to multiply each relative abundance measurement by the total cellular protein per cell. This is the approach taken by *Valgepea et al. (2013)* and *Peebo et al. (2015)*, with relative protein abundances determined based on the relative peptide intensities (label free quantification 'LFQ' intensities). For the data of *Valgepea et al. (2013)*, total protein per cell was determined by measuring total protein by the Lowry method, and counting colony-forming units following serial dilution. For the data from *Peebo et al. (2015)*, the authors did not determine cell quantities and instead report the cellular protein abundances in protein per unit volume by assuming a mass density of 1.1 g/ml, with a 30% dry mass fraction.

A key distinction in the mass spectrometry work of *Schmidt et al. (2016)* is that in addition to determining relative abundance, they performed absolute quantification of 41 enzymes covering over four orders of magnitude in cellular abundance. Here, a synthetic peptide was generated for each of the 41 proteins, doped into each protein sample, and used to provide a calibration between measured mass spectrometry intensities and absolute protein abundances. These absolute measurements, determined for every growth condition considered in their work, were then used as a calibration curve to convert proteomic-wide relative abundances into absolute protein abundance per cell. A more extensive discussion of the *Schmidt et al. (2016)* data set can be found in Section Schmidt *et al.* Proteomic Data Set .

Summary of Proteomic Data Sets.

In *Figure 1* we show the coverage and overlap of all proteins quantified across each data set using an UpSet diagram (*Lex et al., 2014*).

Schmidt *et al.* Proteomic Data Set

While the dataset from Schmidt *et al.* remains a heroic effort that our lab continues to return to as a resource, there were steps taken in their calculation of protein copy number that we felt needed some further consideration. In particular, the authors made an assumption of constant cellular protein concentration across all growth conditions and used measurements of cell volume that appear inconsistent with an expected exponential scaling of cell size with growth rate that is well-documented in *E. coli* (*Schaechter et al. (1958)*; *Taheri-Araghi et al. (2015)*; *Si et al. (2017)*).

We begin by looking at their cell volume measurements, which are shown in blue in Figure 3. As a comparison, we also plot cell sizes reported in three other recent papers: measurements

Figure 1. Comparison of proteomic coverage across different data sets.

Figure 2. Summary of the growth-rate dependent total protein abundance for each data set.

Figure 3. Measurements of cell size as a function of growth rate. (A) Plot of the reported cell sizes from several recent papers. The data in blue come from Volkmer and Heinemann, 2011 (Volkmer and Heinemann (2011)) and were used in the work of Schmidt *et al.*. Data from the lab of Terence Hwa are shown in red (Basan *et al.* (2015)), while the two data sets shown in green and purple come from the lab of Suckjoon Jun (Taheri-Araghi *et al.* (2015); Si *et al.* (2017)). (B) Same as in (A) but with the data plotted on a logarithmic y-axis to highlight the exponential scaling that is expected for *E. coli*.

from Taheri-Araghi *et al.* and Si *et al.* come from the lab of Suckjoon Jun, while those from Basan *et al.* come from the lab of Terence Hwa. Each set of measurements used microscopy and cell segmentation to determine the length and width, and then calculated cell size by treating the cell as a cylinder with two hemispherical ends. While there is a large discrepancy in cell size between the two research groups, Basan *et al.* found that this came specifically from uncertainty in determining the cell width, which is prone to inaccuracy given the small cell size and optical resolution limits (further described in their supplemental text). Perhaps the more concerning point is that while each of these alternative measurements show an exponential increase in cell size at faster growth rates, the measurements used by Schmidt *et al.* appear to plateau. This resulted in an analogous trend in their final reported total cellular protein per cell as shown in Figure 4 (purple data points), and is in disagreement with other measurements of total protein at these growth rates (Basan *et al.* (2015)).

Since it is not obvious how measurements of cell size might have influenced their reported protein abundances, we will go through this calculation in the next section. We will also show how these can be adjusted to better reflect the alternative measurements of cell size shown in Figure 3. Finally, we consider several strategies to adjust the reported copy numbers, with the result summarized in Figure 4. For most growth conditions, we find that total protein expectations are not expected to change dramatically. However, for the fastest growth conditions, with glycerol + supplemented amino acids, and LB media, there is quite a bit of variability among the different estimates.

Effect of cell volume on reported absolute protein abundances in the work of Schmidt *et al.*

The authors calculated proteome-wide protein abundance by first determining absolute abundances of 41 pre-selected proteins, which relied on adding synthetic heavy reference peptides into their protein samples at known abundance (with proteins selected to cover the range of expected copy numbers). This absolute quantitation was performed in replicate for each growth condition. Separately, the authors also performed a more conventional mass spectrometry measurement for samples from each growth condition, which attempted to maximize the number of quantified

Figure 4. Alternative estimates of total cellular protein for the growth conditions considered in Schmidt et al. The original protein mass from Schmidt et al. and Li et al. are shown in purple and blue, respectively. *Green*: Rescaling of total protein mass assuming a growth rate independent protein concentration and cell volumes estimated from Si et al. 2017. *Gold*: Rescaling of total protein mass using estimates of growth rate-dependent protein concentrations and cell volumes estimated from Si et al. 2017. *Red*: Rescaling of total protein mass using the experimental measurements from Basan et al. 2015.

proteins but only provided relative abundances based on peptide intensities. Finally, using their 41 proteins with absolute abundances already determined, they then created calibration curves with which to relate their relative intensity to absolute protein abundance for each growth condition. This allowed them to estimate absolute protein abundance for all proteins detected in their proteome-wide data set. Combined with their flow cytometry cell counts, they were then able to determine absolute abundance of each protein detected on a per cell basis.

While this approach provided absolute abundances, another necessary step needed to arrive at total cellular protein is to account for any protein loss during their various protein extraction steps. Here the authors attempted to determine total protein separately using a BCA protein assay. In personal communications, it was noted that determining reasonable total protein abundances by BCA across their array of growth conditions was particularly troublesome. Instead, they noted confidence in their total protein measurements for cells grown in M9 minimal media + glucose and used this as a reference point with which to estimate the total protein for all other growth conditions.

For cells grown in M9 minimal media + glucose an average total mass of $M_p = 240$ fg per cell was measured. Using their reported cell volume, reported as $V_{orig} = 2.84$ fl, a cellular protein concentration of $[M_p]_{orig} = M_p / V_{orig} = 85$ fg/fl. Now, taking the assumption that cellular protein concentration is relatively independent of growth rate, they could then estimate the total protein mass for all other growth conditions from,

$$M_{p,i} = [M_p]_{orig} \cdot V_i \quad (1)$$

where $M_{p,i}$ represents the total protein mass per cell and V_i is the cell volume for each growth condition i as measured in Volkmer and Heinemann, 2011. Here the thinking is that the values of $M_{p,i}$ reflects the total cellular protein for growth condition i , where any discrepancy from their absolute protein abundance is assumed to be due to protein loss during sample preparation. The protein abundances from their absolute abundance measurements noted above were therefore scaled to their estimates and are shown in Figure 4 (purple data points).

If we instead consider the cell volumes predicted in the work of Si et al., we again need to take

160 growth in M9 minimal media + glucose as a reference with known total mass, but we can follow a
 161 similar approach to estimate total protein mass for all other growth conditions. Letting $V_{Si_glu} = 0.6$
 162 fl be the predicted cell volume, the cellular protein concentration becomes $[M_p]_{Si} = M_p / V_{Si_glu} =$
 163 400 fg/fl. The new total protein mass per cell can then be calculated from,

$$M'_{p_i} = [M_p]_{Si} \cdot V_{Si_i} \quad (2)$$

164 where M'_{p_i} is the new protein mass prediction, and V_{Si_i} refers to the new volume prediction for each
 165 condition i , These are shown as [] dots in Figure 4.

166 **Reconsidering assumption that protein concentration is constant.**

167 We next relax the assumption that cellular protein concentration is constant and instead, attempt
 168 to estimate it using experimental data. Here we first note that for across almost the entire range of
 169 growth rates considered here, protein, DNA, and RNA accounted for at least 90 % of the dry mass in
 170 measurements from the lab of Terence Hwa (*Basan et al. (2015)*). They also found that the total dry
 171 mass concentration was roughly constant across growth conditions. Under such a scenario, we can
 172 calculate the total dry mass concentration for protein, DNA, and RNA, which is given by 1.1 g/ml x
 173 30 % x 90 % or about $[M_p] = 300$ fg per fl. Using the cell volume predictions from *Si et al.*, we can
 174 then calculate the associated mass per cell.

175 However, even if dry mass concentration is relatively constant across growth conditions, it is
 176 not a given that protein concentration should also be constant. In particular, we know that rRNA
 177 increases substantially at faster growth rates (*Dai et al. (2016)*). This is a well-documented result
 178 that arises from an increase in the fraction of ribosomes at faster growth rates (*Scott et al. (2010)*).
 179 To proceed we will use therefore rely on experimental measurements of total DNA content per cell
 180 that also come from *Basan et al.*, and RNA to protein ratios that were measured in *Dai et al.* (and
 181 cover the entire range of growth conditions considered here). These are reproduced in Figure 5(A)
 182 and (B), respectively.

183 Assuming that the protein, DNA, and RNA account for 90 % of the total dry mass, the protein
 184 mass can then determined by first subtracting the experimentally measured DNA mass, and then
 185 using the experimental estimate of the RNA to protein ratio. The total protein per cell is will be
 186 related to the summed RNA and protein mass by,

$$M_p = \frac{[M_p + M_{RNA}]}{1 + (RP_{ratio})} \quad (3)$$

187 (RP_{ratio} refers to the RNA to protein ratio as measured by *Dai et al.*. In Figure 5(C) we plot the
 188 estimated cellular concentrations for protein, DNA, and RNA from these calculations, and in Figure
 189 5(D) we plot their total expected mass per cell.

190 **Estimating cellular protein concentration as a function of growth rate.**

191 One of the challenges in our estimates in the preceding sections is the need to estimate protein
 192 concentration and cell volumes. These are inherently difficult to to accurately due to the small
 193 size of *E. coli*. Indeed, for all the additional measurements of cell volume included in Figure 3, no
 194 measurements were performed for cells growing at rates below 0.5 hr^{-1} . It therefore remains to be
 195 determined whether our extrapolated cell volume estimates are appropriate, with the possibility
 196 that the logarithmic scaling of cell size might break down for slower growth.

197 In our last approach we therefore attempt to estimate total protein using experimental data
 198 that required no estimates of concentration or cell volume. Specifically, in the work of *Basan et al.*
 199 *al.*, the authors measured total protein per cell for a broad range of growth rates (reproduced in
 200 Figure 6). These were determined by first measuring bulk protein from cell lysate, measured by the
 201 colorimetric Biuret method (*You et al. (2013)*), and then abundance per cell was calculated from
 202 cell counts from either plating cells or a Coulter counter. While it is unclear why *Schmidt et al.* was
 203 unable to take a similar approach, the results from *Basan et al* appear more consistent with our

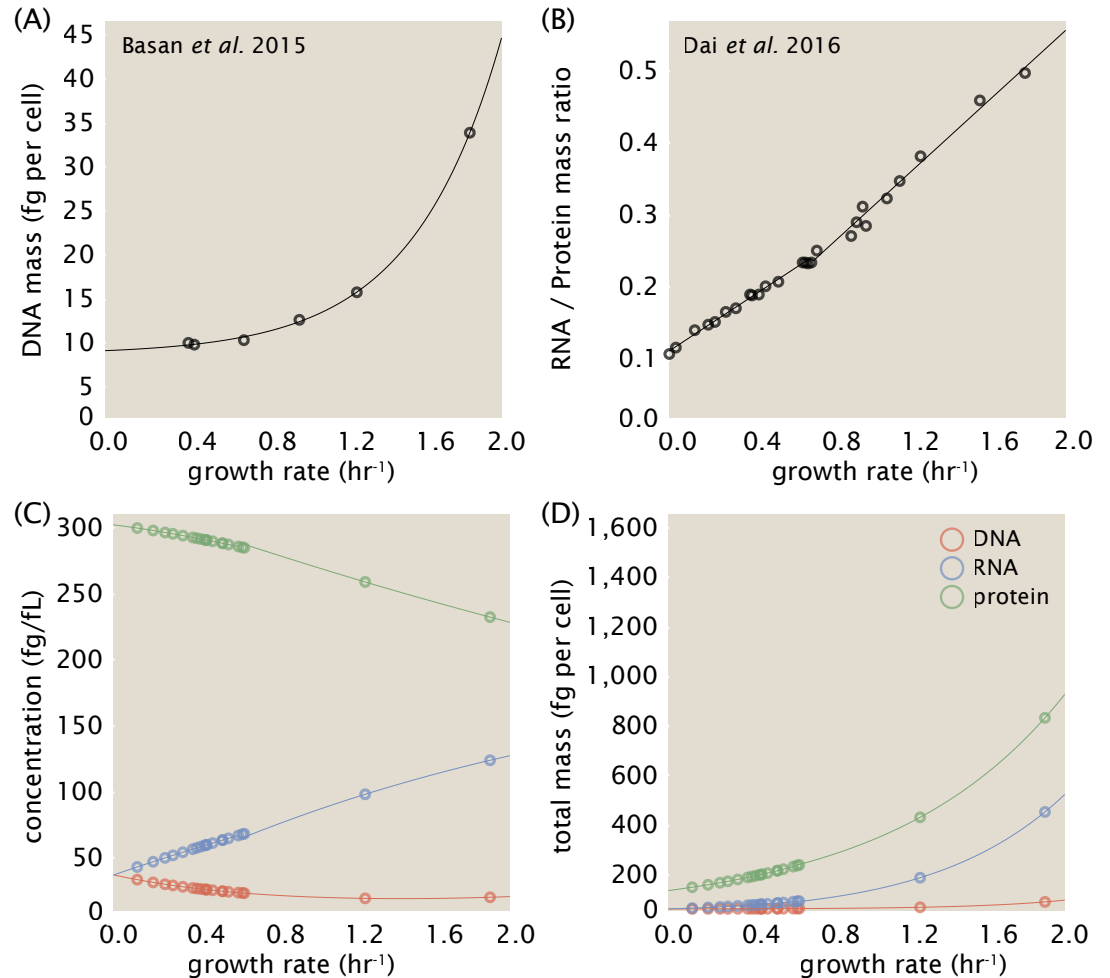

Figure 5. Empirical estimate of cellular protein, DNA, and RNA as a function of growth rate. (A) Measured DNA mass per cell as a function of growth rate, reproduced from Basan *et al.* 2015. The data was fit to an exponential curve (DNA mass in fg per cell is given by $0.42 e^{2.23 \cdot \lambda} + 7.2$ fg per cell, where λ is the growth rate in hr⁻¹). (B) RNA to protein measurements as a function of growth rate. The data was fit to two lines: for growth rates below 0.7 hr⁻¹, the RNA/protein ratio is $0.18 \cdot \lambda + 0.093$, while for growth rates faster than 0.7 hr⁻¹ the RNA/protein ratio is given by $0.25 \cdot \lambda + 0.035$. For (A) and (B) cells are grown under varying levels of nutrient limitation, with cells grown in minimal media with different carbon sources for the slowest growth conditions, and rich-defined media for fast growth rates. (C) Predictions of cellular protein, DNA, and RNA concentration. (D) Total cellular mass predicted for protein, DNA, and RNA using the cell size predictions from Si *et al.*

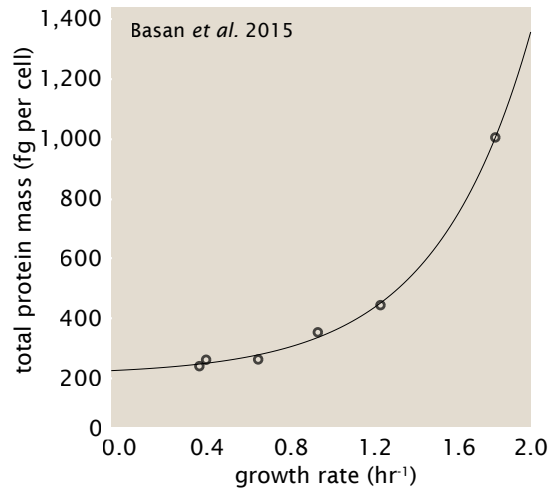

Figure 6. Total cellular protein reported in Basan *et al.* 2015. Measured protein mass as a function of growth rate as reproduced from Basan *et al.* 2015, with cells grown under different levels of nutrient limitation. The data was fit to an exponential curve where protein mass in fg per cell is given by $14.65 e^{2.180 \cdot \lambda} + 172$ fg per cell, where λ is the growth rate in hr^{-1}).

204 expectation that cell mass will increase exponentially with faster growth rates. In addition, although
 205 they do not consider growth rates below about 0.5 hr^{-1} , it is interesting to note that the protein
 206 mass per cell appears to plateau to a minimum value at slow growth. In contrast, our estimates
 207 using cell volume so far have predicted that total protein mass should continue to decrease slightly
 208 for slower growing cells. By fitting this data to an exponential function dependent on growth rate,
 209 we could then estimate the total protein per cell for each growth condition considered by Schmidt
 210 *et al.*. These are plotted in red in Figure 4.

211 Estimation of cell size and surface area across all growth conditions.

In Figure 3 we looked at a number of recent cell size measurements and potential issues with the values used by Schmidt *et al.*. Since most of the proteomic data sets lack cell size measurements, we chose instead to use a common set of size measurements for any analysis requiring cell size or surface area. Since each of the data sets used either K-12 MG1655 or its derivative, BW25113 (from the lab of Barry L. Wanner; the parent strain of the Keio collection (*Datsenko and Wanner, 2000; Baba et al., 2006*)), we fit the MG1655 cell size data from Si *et al.* 2017, 2019 using the `optimize.curve_fit` function from the `Scipy` python package (Virtanen *et al.*, 2020).

212 The size data is shown in Figure 7)(A) and (B), for the cell length and width, respectively. The
 213 length data was well described by the exponential function $0.5 e^{1.09 \cdot \lambda} + 1.76 \mu\text{m}$, while the width data
 214 was well described by $0.64 e^{0.24 \cdot \lambda} \mu\text{m}$. In order to estimate cell size we take the cell as a cylinders
 215 with two hemispherical ends (Si *et al., 2017; Basan et al., 2015*). Specifically, cell size (or volume) is
 216 estimated from,

$$V = \pi \cdot r^2 \cdot (l - 2r/3), \quad (4)$$

217 where r is half the cell width. A best fit to the data is described by $0.533 e^{1.037 \cdot \lambda} \mu\text{m}^3$. Calculation of
 218 the cell surface area is given by,

$$S = \eta \cdot \pi \left(\frac{\eta \cdot \pi}{4} - \frac{\pi}{12} \right)^{-2/3} V^{2/3}, \quad (5)$$

219 where η is the aspect ratio ($\eta = l/w$) (Ojkic *et al., 2019*).

Figure 7. Summary of size measurements from Si et al. 2017, 2019. Cell lengths and widths were measured from cell contours obtained from phase contrast images, and refer to the long and short axis respectively. (A) Cell lengths and (B) cell widths show the mean measurements reported (they report 140-300 images and 5,000-30,000 for each set of samples; which likely means about 1,000-5,000 measurements per mean value reported here since they considered about 6 conditions at a time). Fits were made to the MG1655 strain data; length: $0.5 e^{1.09 \cdot \lambda} + 1.76 \mu\text{m}$, width: $0.64 e^{0.24 \cdot \lambda} \mu\text{m}$. (C) Cell size, V , was calculated as cylinders with two hemispherical ends (Equation 4). The MG1655 strain data gave a best fit of $0.533 e^{1.037 \cdot \lambda} \mu\text{m}^3$.

Extending Estimates to a Continuum of Growth Rates

In the main text, we considered a standard stopwatch of 5000 s to estimate the abundance of the various protein complexes considered. In addition to point estimates, we also showed the estimate as a function of growth rate as transparent grey curves. In this section, we elaborate on this continuum estimate and compare and contrast the approach to the point estimate procedure.

Estimation of the total cell mass

For many of the processes estimated in the main text we relied on a cellular dry mass of ≈ 300 fg from which we computed elemental and protein fractions using knowledge of fractional composition of the dry mass. At modest growth rates, such as the 5000 s doubling time used in the main text, this is a reasonable number to use as the typical cell mass is ≈ 1 pg and *E. coli* cells can be approximated as 70% water by volume. However, as we have shown in this supplemental information, the cell size and therefore cell volume is highly dependent on the growth rate. This means that a dry mass of 300 fg cannot be used reliably across all growth rates.

Rather, using
